Chapter 8: Sorting in Linear Time
Lower Bound for Sorting

Comparison sort: A sorting algorithm is based only on comparisons between the input elements.

Comparison sorts can be viewed abstractly in terms of decision trees.

Decision trees: Given an input sequence $< a_1, a_2, \ldots, a_n >$,

- Each internal node is denoted by $a_i : a_j$, for $1 \leq i, j \leq n$.

- Each leaf node is denoted by a permutation $< \pi(1), \pi)2), \ldots, \pi(n) >$.

- Each path from the root to a leaf corresponds to an execution of the sorting algorithm for a specific input.

- The left branch of an internal node means $a_i \leq a_j$.
  The right branch for an internal node means $a_i > a_j$.

- There are $n!$ permutations for n elements $\Longrightarrow$ there are at least $n!$ leaf nodes.

```
Ex: The decision tree for insertion sort with 3 elements.
                  a1:a2
               /          \
          a2:a3             a1:a3
         /     \           /      \
     <1,2,3>  a1:a3   <2,1,3>     a2:a3
            /     \             /      \
        <1,3,2> <3,1,2>     <2,3,1> <3,2,1>

Ex: The decision tree for selection sort with 3 elements.
                  a1:a2
               /          \
          a1:a3             a2:a3
         /     \           /      \
     a2:a3    a1:a2     a1:a3     a1:a2
    /    \    /        /     \         \
<1,2,3> <1,3,2> <3,1,2>  <2,1,3> <2,3,1>  <3,2,1>
```
There are $n!$ permutations for n elements $\Longrightarrow$ the tree has at least $n!$ leaves.
Let h be the height of the tree $\Longrightarrow$ the tree has no more than 2^h leaves.
Thus,
$$n! \leq 2^h \Longrightarrow h \geq \log(n!) \Longrightarrow h = \Omega(n\log n)$$
The height of a decision tree means the number of comparisons for sorting in the worst-case.

$\Longrightarrow$ All comparison sorts have a lower bound running time $\Omega(n\log n)$ for the worst-case.

$\Longrightarrow$ It is impossible to find a new comparison based sorting algorithm that is asymptotically better than merge sort.

However, some non-comparison based sorting algorithms may run in linear time.

Counting Sort

Counting sort assumes that each of the n input elements is an integer within a range $[0..k]$, for some integer k.

An input array $A[1:n]$, an output array $B[1:n]$, and a temporary working storage $C[0:k]$ are necessary for this algorithm. Thus, counting sort does not sort in place.

During the execution of counting sort, $C[i]$ maintains the # of elements less than or equal to i. For each element j in A, put it into B at position $C[j]$.

```
Counting-Sort(A, n, k)
1.   let B[1:n] and C[0:k] be new arrays
2.   for i = 0 to k
3.       C[i] = 0
4.   for j = 1 to n
5.       C[A[j]] = C[A[j]] + 1
6.   // C[i] contains the # of elements that is equal to i
7.   for i = 1 to k
8.       C[i] = C[i] + C[i-1]
9.   // C[i] now contains the # of elements less than or equal to i
10. // Copy A to B, starting from the end of A
11. for j = n downto 1
10.      B[C[A[j]]] = A[j]
11.      C[A[j]] = C[A[j]] - 1 // to handle duplicate values
```

(f)

- Running time analysis:

  Counting-Sort's running time is $\Theta(n+k)$.

  If $k = O(n)$, then $\Theta(n+k) = \Theta(n)$. It's a linear time!

- Counting sort is a **stable** sorting algorithm: elements with the same value in the output array should be in the same order as they do in the input array.

  - Insertion Sort: stable (if no "=" sign in comparison)

  - Selection Sort: stable (if no "=" sign in comparison)

  - Merge Sort: stable (if the "=" sign is in the comparison)

  - Heap Sort: not stable (exchange $A[1] \longrightarrow A[n]$)

  - Quick Sort: not stable.
    Ex: input: $< 5, 5', 5'', 3, 4 >$ and the output is $< 3, 4, 5'', 5, 5' >$.

3

Radix Sort

The Radix-Sort sorts by the least significant digit first, then by the 2nd least significant digit, ….

The sorting algorithm used to sort each digit should be stable; otherwise Radix-Sort will not work.

```
Ex:
    213              321              312              123
    312              312              212              132
    123              212              213              212
    212  stable      132  stable      321  stable      213
    321  ------>     213  ------>     123  ------>      312
    132              123              132              321
     ^                ^                ^
```

```
Ex:
    213              321                 312              123
    312              312                 213 <-           132
    123              212                 212 <-           213 <-
    212  stable      132  not stable     321  stable      212 <-
    321  ------>     213  ---------->    123  ------>      312
    132              123                 132              321
     ^                ^                   ^
```

Another example:

```
329      720      720      329
457      355      329      355
657      436      436      436
839  →   457  →   839  →   457
436      657      355      657
720      329      457      720
355      839      657      839
```

```
Radix-Sort(A, d)
1. for i = 1 to d
2.     use a stable sort to sort array A[1:n] on digit i
```

Two questions:

- Why does the algorithm need to use a stable sort to sort each digit?

- Why does the sorting start from sorting the least significant digit first?

`Running time analysis`: Suppose all n numbers have d or less digits.

If we use Counting-Sort as the sorting algorithm to sort each digit, then the running time for Radix-Sort is $d \cdot \Theta(n+k) = \Theta(dn+dk)$

If $k = O(n)$ and d is a constant, then the running time becomes $\Theta(n)$.

It's a linear time!

Recommended Exercise: Show how to sort n integers in the range 0 to $n^2 - 1$ in $O(n)$ time.

Solution:

We will assume that each digit has value in the range $0..n-1$, that is $k = n$. That is, as if the numbers are written in radix-n or base-n (instead of the usual base 2 or base 10).

Counting sort now requires $O(n+k) = O(n)$ time.

Then each number will have two digits, so $d = 2$ as the range of the numbers is $[0..n^2 - 1]$.

Since $d = 2$, radix-sort requires two passes of Counting sort that each take $O(n)$ time. This the total run-time for radix-sort for this type of input is $O(n)$.
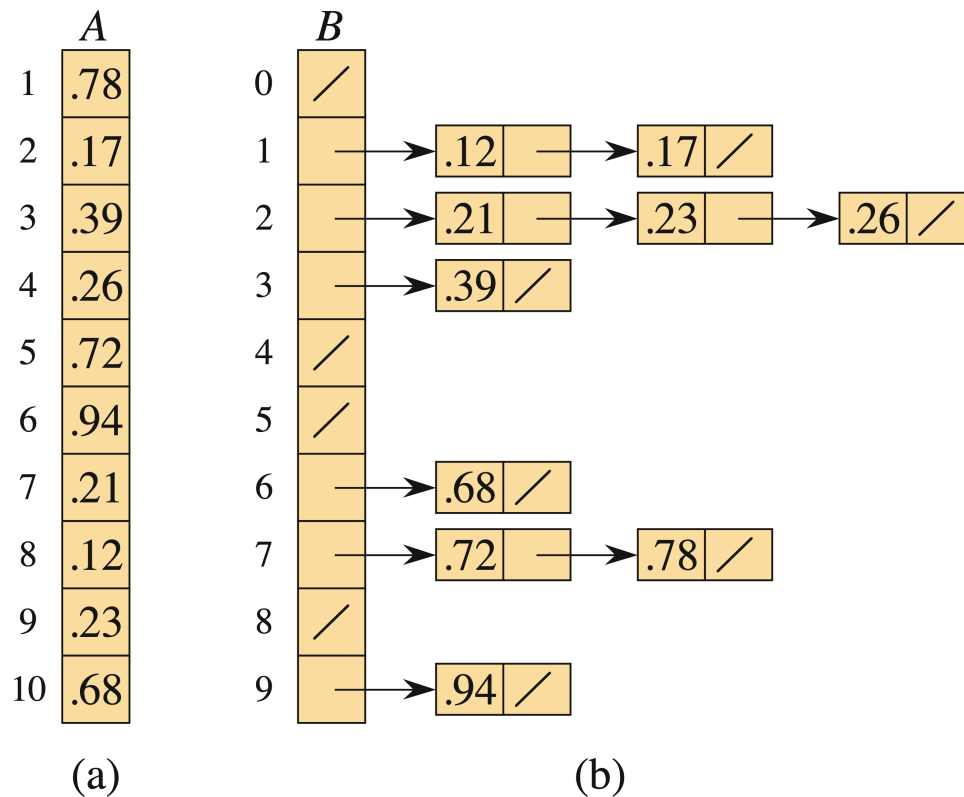

Bucket sort

Assumption: input is drawn from the range $[0..1)$ with a uniform probability distribution.

Average case is $O(n)$.

```
Bucket-Sort(A, n)
1.   let B[0..n-1] be a new array
2.   for i = 0 to n - 1
3.       make B[i] an empty list
4.   for i = 1 to n
5.       insert A[i] into list B[floor(n A[i])]
6.   for i = 0 to n - 1
7.       sort B[i] using insertion sort
8.   concatenate the lists B[0], B[1],...,B[n-1] together in order
9.   return the concatenated lists
```

A

1	.78
2	.17
3	.39
4	.26
5	.72
6	.94
7	.21
8	.12
9	.23
10	.68

(a)

B

0	
1	→ .12 → .17
2	→ .21 → .23 → .26
3	→ .39
4	
5	
6	→ .68
7	→ .72 → .78
8	
9	→ .94

(b)

If each list is of size $O(1)$, then the run-time is $O(n)$. The average case analysis requires advanced math so we will skip it here.

Notes: If the key values are uniformly distributed, we can still get $O(n)$ average case run time if we know the probability distribution. How can we take advantage of knowing the probability distribution to get all buckets to be of size $O(1)$ on the average?
